Recap

Process data structures:

- User space
- PCB (process control block)

Multiprogramming:

- Scheduler, Process states/queues
- Context switch

Process API: fork, wait, exec, pipe, dup xv6-riscv

L3: Limited Direct Execution

(Based on Chapter 6)

Spring 2023

How to run processes?

Direct Execution (without limits)

OS

Process

- 1. Create entry for process
- 2. Allocate memory for program
- 3. Load program into memory
- 4. Set up stack (argc and argv parameters for main)
- 5. Clear registers
- 6. Execute **call** main()

- 1. Run main()
- 2. Execute **return** from main

- 1. Free memory of process
- 2. Remove from process list

What is wrong?

- Process has unrestricted access to memory and other resources.
- OS has no way to switch another process, must wait for program to finish.

How to restrict process' operations?

Restricting Access with Processor Mode

CPU has bit that indicates if in user mode or kernel mode

When in user mode, "privileged" instructions not allowed and memory boundaries are enforced

Cannot read/write outside of address space bounds

Cannot read/write I/O devices

When in kernel mode, all instructions are allowed

User processes only execute in user mode, the OS executes in kernel mode

Processor Mode

Kernel Mode

Process User Mode

- 1. Create entry for process
- 2. Allocate memory for program
- 3. Load program into memory
- 4. Set up stack (argc and argv parameters for main
- 5. Clear registers
- 6. Execute **call** main()

enter user mode

enter kernel mode

- 1. Run main()
- 2. Execute **return** from main

1. Free memory of process

2. Remove from process list

Process can't access out of its memory space and can't read/write I/O devices

System Call

Problem: How can a process perform privileged operations, for example read from a file? System call!

If no different modes, user could just make a functional call to "kernel" libraries.

A system call differs from a normal function call: it transfers control to the OS.

A user process initiates a system call by causing a *trap* (a software generated interrupt)

For example, the RISC V instruction that causes a trap is ecall

System Call

OS Kernel Mode

Hardware

Process

User Mode

Initialize process and return-from-trap into main()

Return-from-trap changes mode to user

Trap changes mode to kernel

- 1. Run main()
- 2. System call causes trap

- 1. Handle trap
 - ...
- 2. return-from-trap

Return-from-trap changes mode to user

Trap changes mode to kernel

- • •
- I. Call **exit**() system call
- 2. System call traps into OS

Free memory and remove process

System Call Details

S Kernel Mode

Hardware

Process User Mode

- 1. Create entry for process
- 2. Allocate memory for program
- 3. Load program into memory
- 4. Set up stack (argc and argv parameters for main)
- 5. Clear registers
- 6. return-from-trap

- 1. Move to user mode
- 2. Jump to main
- 1. Save regs (**PC**, etc.) to kernel stack
- 2. Move to kernel mode
- Jump to trap handler

- 1. Run main()
 - •••
- 2. Call system call
- 3. System call traps into OS

- 1. Handle trap
 - • •
- 2. return-from-trap

- . Restore regs from kernel stack
- 2. Move to user mode
- 3. Jump to PC after trap

- ...
- 1. Run main()
- 2. Call exit() system call
- 3. System call traps into OS

- 1. Free memory of process
- 2. Remove from process list

Process Control Block (struct proc) in xv6

```
proc.h
// Saved registers for kernel context switches. // Per-process state
struct context {
                                               struct proc {
                                                 struct spinlock lock;
 uint64 ra;
 uint64 sp;
                                                 // p->lock must be held when using these:
 // callee-saved
                                                 enum procstate state;
                                                                             // Process state
 uint64 s0:
                                                 void *chan;
                                                                             // If non-zero, sleeping on channel
 uint64 s1:
                                                 int killed;
                                                                             // If non-zero, have been killed
                                                                              // Exit status to be returned to parent's wait
 uint64 s2:
                                                 int xstate;
                                                                              // Process ID
 uint64 s3:
                                                 int pid;
 uint64 s4;
 uint64 s5;
                                                 // proc tree lock must be held when using this:
 uint.64 s6:
                                                 struct proc *parent;
                                                                             // Parent process
 uint64 s7;
 uint64 s8;
                                                 // these are private to the process, so p->lock need not be held.
 uint64 s9;
                                                 uint64 kstack;
                                                                             // Virtual address of kernel stack
 uint64 s10;
                                                 uint64 sz:
                                                                             // Size of process memory (bytes)
 uint64 s11;
                                                 pagetable t pagetable;
                                                                             // User page table
                                                 struct trapframe *trapframe; // data page for trampoline.S
};
                                                 struct context context;
                                                                             // swtch() here to run process
enum procstate { UNUSED, USED, SLEEPING,
                                                 struct file *ofile[NOFILE]; // Open files
                                                 struct inode *cwd;
                                                                             // Current directory
RUNNABLE, RUNNING, ZOMBIE };
                                                 char name[16];
                                                                              // Process name (debugging)
                                                                                                                11
                                                };
```

System Call Details: trap table

OS Kernel Mode

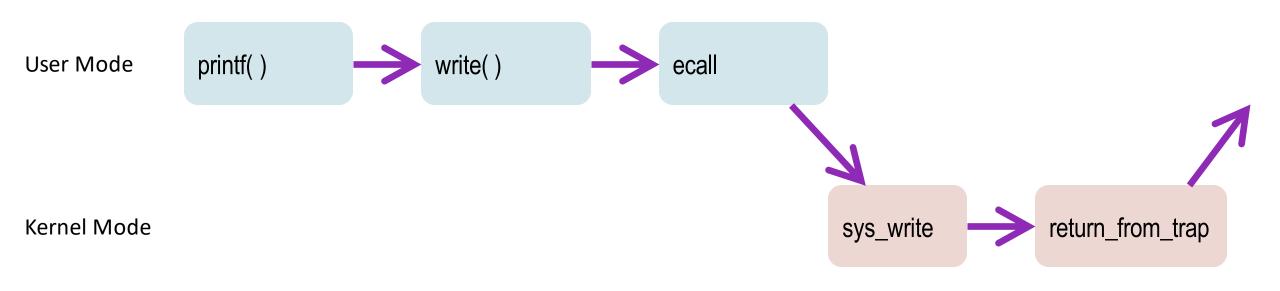

Hardware

Initialize trap table (map: interrupt number -> address of interrupt handler)

Remember address of syscall handler

System Call Example

Library functions like printf typically have some code that executes in user mode, it then makes one or more system calls.

How to switch between process?

More fundamentally, how the OS can regain the control after it starts a process?

A Cooperative Approach: Wait for System Calls

A well-behaving process makes a *yield* system call after it has executed for a while.

A process initializes an I/O operation by making a system call (e.g., read, write).

Once trap to OS: scheduler can switch process.

A Non-cooperative Approach: Timer Interrupt

Hardware

Initialize trap table (map: interrupt number ==> address of interrupt handler)

Remember address of syscall handler

Start interrupt timer

Start timer
Interrupt CPU in X ms

OS Regain Control via Timer Interrupt

Kernel Mode

Handle the trap
Call switch() routine:
Save regs(A) -> proc_t(A)
Restore regs(B) <- proc_t(B)
Switch to kernel-stack(B)
return-from-trap (into B)

Hardware

Timer interrupt
Save regs(A) -> kernel-stack(A)
Move to kernel mode
Jump to trap handler

Process

Process A

User Mode

... ...

Restore regs(B) <- kernel-stack(B)

Move to user mode Jump to B's PC

Process B

... ...

Process Control Block (struct proc) in xv6

```
proc.h
// Saved registers for kernel context switches. // Per-process state
struct context {
                                               struct proc {
                                                 struct spinlock lock;
 uint64 ra:
 uint64 sp;
                                                 // p->lock must be held when using these:
  // callee-saved
                                                 enum procstate state;
                                                                             // Process state
 uint64 s0;
                                                 void *chan;
                                                                             // If non-zero, sleeping on channel
 uint64 s1:

Limited Direct Execution

Time-sharing is the idea that multiple processes can run together on a single machine as though they are in sole control of the machine

How do processes share time?

multiprogramming – when a process waits for I/O, the OS can have another take over the CPU

multitasking – each process gets a time-slice, a time limit before the next process gets to execute on the CPU

How does the OS keep control?

Hardware provides *interrupts*, *kernel mode* and *user mode*

System calls (cooperative) and interrupts (non-cooperative) enable OS to regain control after starting a process.
